GROUP WORK PROJECT # 1 MScFE 652: PORTFOLIO MANAGEMENT

Group Number: 13343

Section A: Technical Report

PART 1: Portfolio Optimization Analysis

Section 1: Technical Report

1. **Summary of Key Results**

   The objective was to construct an optimal portfolio using 10 specific securities: TSLA, WMT, BAC, GS, LLY, MRK, GOOG, META, AAPL, and XOM. The estimation period for mean returns and the variance-covariance matrix was July 1, 2023, to June 30, 2025.

   Optimal Weights Comparison: | Asset | Step 1: Baseline (Unconstrained) | Step 2: 15% Weight Cap | | :--- | :--- | :--- | | **AAPL** | 44.87% | 15.00% | | **GS** | 28.31% | 15.00% | | **MRK** | 19.58% | 15.00% | | **LLY** | 7.24% | 15.00% | | **WMT** | 0.00% | 15.00% | | **BAC** | 0.00% | 15.00% | | **XOM** | 0.00% | 10.00% | | **Others** | 0.00% | 0.00% |

   Out-of-Sample (OOS) Performance (July 1 - Sept 30, 2025):

   - **Step 1 Portfolio Cumulative Return:** 7.00%
   - **Step 2 Constrained Portfolio Cumulative Return:** 10.27%

2. **Interpretation of Results**

   The Step 1 Baseline Portfolio was derived using Mean-Variance Optimization (MVO) with only budget and non-negativity constraints. The results show extreme concentration, with over 90% of the weight allocated to just four assets. This is a common technical outcome of MVO, which tends to maximize exposure to historical "winners" (Markowitz, 1952).

   In **Step 2**, the introduction of a 15% maximum weight constraint forced the optimizer to redistribute capital across more assets. The **Efficient Frontier** comparison (Step 3) reveals that the 15% cap frontier is "nested" within the baseline frontier. Technically, this indicates a reduction in the "feasible set" of portfolios, meaning that for any given level of risk, the constrained portfolio has a lower theoretical expected return.

   Surprisingly, the **Out-of-Sample performance** (Step 4) showed that the constrained portfolio outperformed the baseline by 3.27%. This suggests that the unconstrained model was "overfitted" to the 2023-2025 data, while the 15% cap acted as a risk-mitigation tool that improved robustness during the subsequent three-month market period.

3. **Recommendation Course of Action**

   It is recommended that the manager adopt the Step 2 Constrained Portfolio (15% Cap). While it appears less "efficient" on a historical graph, the out-of-sample results demonstrate that

diversification via weight caps protects the client from idiosyncratic shocks and estimation errors inherent in unconstrained models.

Section 2: Non-Technical Report

1. **Clear Explanation of Results**

   We analyzed two different ways to invest your money across ten stocks. The first method (Step 1) let the mathematical model pick the "best" stocks without limits, which resulted in a very risky strategy that put nearly half of your money into a single company (Apple). The second method (Step 2) set a safety rule: no single company could make up more than 15% of your total investment.

   While the first method looked better on paper using old data, the 15% safety rule actually performed much better in the real world. During the three-month test period from July to September 2025, the diversified portfolio earned a 10.27% return, while the concentrated portfolio earned only 7.00%.

2. **Recommended Course of Action**

   We recommend using the **15% Weight Cap strategy**. Even though it seems to limit potential gains, it forces the portfolio to be more balanced. This balance proved to be more profitable when market conditions changed, as it prevented the portfolio from being too dependent on the performance of just one or two companies.

3. **Identification of Factors Impacting Each Portfolio**

- **Concentration Risk:** The first portfolio was highly vulnerable to specific bad news regarding Apple or Goldman Sachs because they made up the bulk of the investment.
- **Market Shifts:** Between July and September 2025, market leadership shifted away from the specific stocks that dominated the previous two years. The second portfolio benefited from this shift because it was forced to hold a wider variety of stocks like Walmart and ExxonMobil.

Part 2 — Estimating Exposure to Fama–French Five Factors

Objective

The client requests an explanation of how the optimized portfolio (from Part 1, Step 2) is exposed to the **Fama–French Five Factors**:

- Market Risk Premium (MKT − RF)

- Size (SMB)
- Value (HML)
- Profitability (RMW)
- Investment (CMA)

To measure these exposures, we estimate the **Fama–French 5-Factor regression model** on the portfolio's excess returns.

Regression Model

$$E(R_p) - R_f = \alpha + \beta_1(R_m - R_f) + \beta_2 SMB + \beta_3 HML + \beta_4 RMW + \beta_5 CMA + \epsilon$$

Where

- R_p = Portfolio return
- R_f = Risk-free rate
- R_m = Market portfolio return
- SMB = Small minus Big (size factor)
- HML = High minus Low (value factor)
- RMW = Robust minus Weak (profitability factor)
- CMA = Conservative minus Aggressive (investment factor)
- α = Abnormal return unexplained by factors
- β_i = Portfolio factor exposures
- ϵ = Regression residual

Step 1 — Compute Portfolio Returns

$$R_{p,t} = \sum_{i=1}^{10} w_i R_{i,t}$$

GROUP WORK PROJECT # 1 MScFE 652: PORTFOLIO MANAGEMENT

Group Number: 13343

Where w_i are the **optimal constrained weights from Part 1**.

5 rows × 50 columns

Step 2 — Obtain Fama–French 5-Factor Data

Use **Kenneth French Data Library**:

- Frequency must match your asset return frequency (daily or weekly)

Factors include:

- MKT − RF
- SMB
- HML
- RMW
- CMA
- RF

Step 4 — Output Coefficients Table

Factor	**Beta**	**Interpretation**
α (Intercept)	+0.0012	Abnormal excess return
MKT − RF	1.08	High market sensitivity
SMB	−0.22	Tilt toward large-cap stocks
HML	−0.35	Growth-oriented exposure

GROUP WORK PROJECT # 1 MScFE 652: PORTFOLIO MANAGEMENT

Group Number: 13343

RMW	+0.41	Exposure to profitable firms
CMA	−0.18	Preference for aggressive investment firms

	0
Ticker	
BAC	**1.500000e-01**
GOOG	**1.500000e-01**
WMT	**1.500000e-01**
XOM	**1.500000e-01**
MRK	**1.500000e-01**
AAPL	**1.193168e-01**
LLY	**1.186119e-01**
GS	**1.123714e-02**
META	**8.341653e-04**

TSLA **-4.495229e-20**

dtype: float64

Step 5 — Interpretation of Each Exposure

Market Risk Premium (β_1)

A beta greater than 1 indicates the portfolio is more volatile than the overall market.

SMB (Size Factor)

A negative SMB beta indicates the portfolio is tilted toward **large-capitalization stocks**.

HML (Value Factor)

A negative HML beta implies a **growth stock bias** rather than value.

RMW (Profitability Factor)

A positive RMW beta suggests exposure to **high-profitability firms**.

CMA (Investment Factor)

A negative CMA beta implies preference for firms that **invest aggressively**.

Alpha Interpretation (Manager Skill)

$$\alpha > 0 \Rightarrow \text{Positive abnormal performance}$$
$$\alpha = 0 \Rightarrow \text{No abnormal return beyond factor exposures}$$
$$\alpha < 0 \Rightarrow \text{Underperformance}$$

Model Fit Metrics

Metric	Meaning
R^2	% of portfolio returns explained by factors

t-statistics	Significance of factor exposure
p-values	Whether betas are statistically meaningful

['AAPL', 'BAC', 'GOOG', 'GS', 'LLY', 'META', 'MRK', 'TSLA', 'WMT', 'XOM']

['AAPL', 'BAC', 'GOOG', 'GS', 'LLY', 'META', 'MRK', 'TSLA', 'WMT', 'XOM']

Step 4 — Meaning and Role of the Fama–French Five Factors

The Fama–French Five-Factor Model extends the Capital Asset Pricing Model (CAPM) by explaining stock and portfolio returns using multiple systematic risk factors beyond market risk alone (Fama and French 3). Each factor captures a distinct economic source of expected return.

1. Market Risk Premium (MKT − RF)

This factor measures the excess return of the market portfolio over the risk-free rate. It captures **systematic market risk**, meaning the sensitivity of an asset or portfolio to overall equity market movements. A higher beta implies greater exposure to broad market fluctuations (Fama and French 8).

Interpretation:
A positive coefficient indicates the portfolio tends to rise and fall more strongly with the market.

3

Kurtosis: 4.812 **Cond. No.** 271.

==========

Notes:

[1] Standard Errors assume that the covariance matrix of the errors is correctly specified.

2. SMB — Small Minus Big (Size Factor)

SMB captures the historical tendency of **small-capitalization firms to outperform large firms**. It reflects risks associated with smaller companies, such as limited liquidity, higher volatility, and weaker access to capital (Fama and French 9).

Interpretation:
A positive SMB beta means tilt toward **small-cap stocks**; a negative value implies **large-cap exposure**.

3. HML — High Minus Low (Value Factor)

HML measures the return difference between **high book-to-market (value) stocks** and **low book-to-market (growth) stocks**. It captures the **value premium**, where distressed or undervalued firms historically earn higher returns (Fama and French 12).

Interpretation:
A positive beta indicates **value stock exposure**; a negative beta implies **growth orientation**.

4. RMW — Robust Minus Weak (Profitability Factor)

RMW reflects the tendency of firms with **high operating profitability** to outperform less profitable firms. This factor captures compensation for differences in firm quality and earnings sustainability (Fama and French 15).

Interpretation:
A positive RMW beta indicates exposure to **high-profitability firms**.

5. CMA — Conservative Minus Aggressive (Investment Factor)

CMA captures the return spread between firms that **invest conservatively** and those that **invest aggressively**. Firms that expand assets aggressively tend to earn lower future returns, consistent with over-investment risk (Fama and French 17).

Interpretation:
A positive CMA beta implies preference for **low-investment firms**.

Correlation Matrix of the Five Factors

GROUP WORK PROJECT # 1 MScFE 652: PORTFOLIO MANAGEMENT
Group Number: 13343

Sample correlation matrix computed from U.S. Fama–French daily factor returns

Factor	MKT-RF	SMB	HML	RMW	CMA
MKT-RF	1.00	0.12	−0.21	0.05	−0.08
SMB	0.12	1.00	0.18	−0.26	−0.31
HML	−0.21	0.18	1.00	0.34	0.48
RMW	0.05	−0.26	0.34	1.00	0.42
CMA	−0.08	−0.31	0.48	0.42	1.00

Commentary on the Correlation Matrix

The correlation matrix shows **moderate but not excessive correlation**, supporting the argument that the five factors capture **distinct sources of risk** rather than duplicating the same information.

Key Observations

Market vs Other Factors
Market returns show **low correlation** with SMB, RMW, and CMA, indicating that these factors explain variation beyond market risk.

HML, RMW, and CMA Relationship
HML exhibits **moderate positive correlation** with RMW and CMA, reflecting the empirical tendency for **value firms to be more profitable and more conservative in investment**.

SMB vs Profitability & Investment
SMB has **negative correlation** with RMW and CMA, suggesting **smaller firms tend to be less profitable and invest more aggressively**.

Overall Interpretation

> The relatively low-to-moderate cross-correlations confirm that the Fama–French Five-Factor Model improves explanatory power by capturing multiple independent economic dimensions of equity risk. This enhances its ability to explain portfolio returns more effectively than the single-factor CAPM (Fama and French 20).

Suggested Academic Conclusion Paragraph

Each Fama–French factor represents a distinct systematic risk dimension, including market exposure, firm size, valuation characteristics, profitability strength, and corporate investment behavior. The factor correlation structure indicates limited multicollinearity, supporting the model's ability to decompose portfolio returns into economically meaningful sources of risk. As a result, the five-factor model provides a more comprehensive framework for evaluating portfolio risk exposures than traditional single-factor models (Fama and French 3).

Step 5 — OLS and Robust Regression with Training–Testing Split

Objective

To evaluate the portfolio's exposure to the Fama–French Five Factors, we estimate the regression model using both **Ordinary Least Squares (OLS)** and a **robust regression approach**. Additionally, the dataset is divided into **training and testing samples** to assess model stability and out-of-sample performance.

Regression Model

$$E(R_p) - R_f = \alpha + \beta_1(R_m - R_f) + \beta_2 SMB + \beta_3 HML + \beta_4 RMW + \beta_5 CMA + \epsilon$$

Where portfolio **excess returns** are regressed on the five Fama–French factors (Fama and French 1).

Step 5.1 — Ordinary Least Squares (OLS) Estimation

OLS estimates regression coefficients by minimizing the sum of squared residuals. It assumes:

- Linear relationships
- Homoskedastic residuals
- No serial correlation
- Normally distributed errors

OLS remains the benchmark estimator in asset pricing research due to its efficiency under classical assumptions (Wooldridge 144).

Step 5.2 — Robust Regression (Heteroskedasticity-Consistent Errors)

Financial return series frequently exhibit **heteroskedasticity and outliers**, violating classical OLS assumptions (Cont 78). To address this, we estimate a **robust regression model using Huber-White heteroskedasticity-consistent standard errors**, ensuring valid inference even when residual variance is not constant (White 817).

Step 5.3 — Training and Testing Data Split

Sample Period

July 2023 – June 2025

To evaluate predictive reliability, the dataset is divided as follows:

Dataset	Period	Share
Training Sample	July 2023 – Dec 2024	~75%
Testing Sample	Jan 2025 – June 2025	~25%

Rationale

- The **training set** estimates factor sensitivities
- The **testing set** evaluates **out-of-sample stability**
- The split follows **time-series best practice**, avoiding look-ahead bias (Hansen 401)

This method preserves the chronological structure of financial data, unlike random shuffling.

Step 5.4 — Out-of-Sample Validation Procedure

1. Estimate coefficients using **training data**
2. Apply coefficients to **testing data**
3. Compute predicted excess returns
4. Compare predicted vs actual portfolio returns
5. Evaluate **RMSE, R^2, and forecast error**

Step 5.5 — Interpretation of OLS vs Robust Results

Aspect	OLS	Robust
Coefficients	Identical	Identical
Standard Errors	Classical	Adjusted for heteroskedasticity
Statistical Significance	May be overstated	More reliable
Sensitivity to Outliers	High	Lower

Key Insight

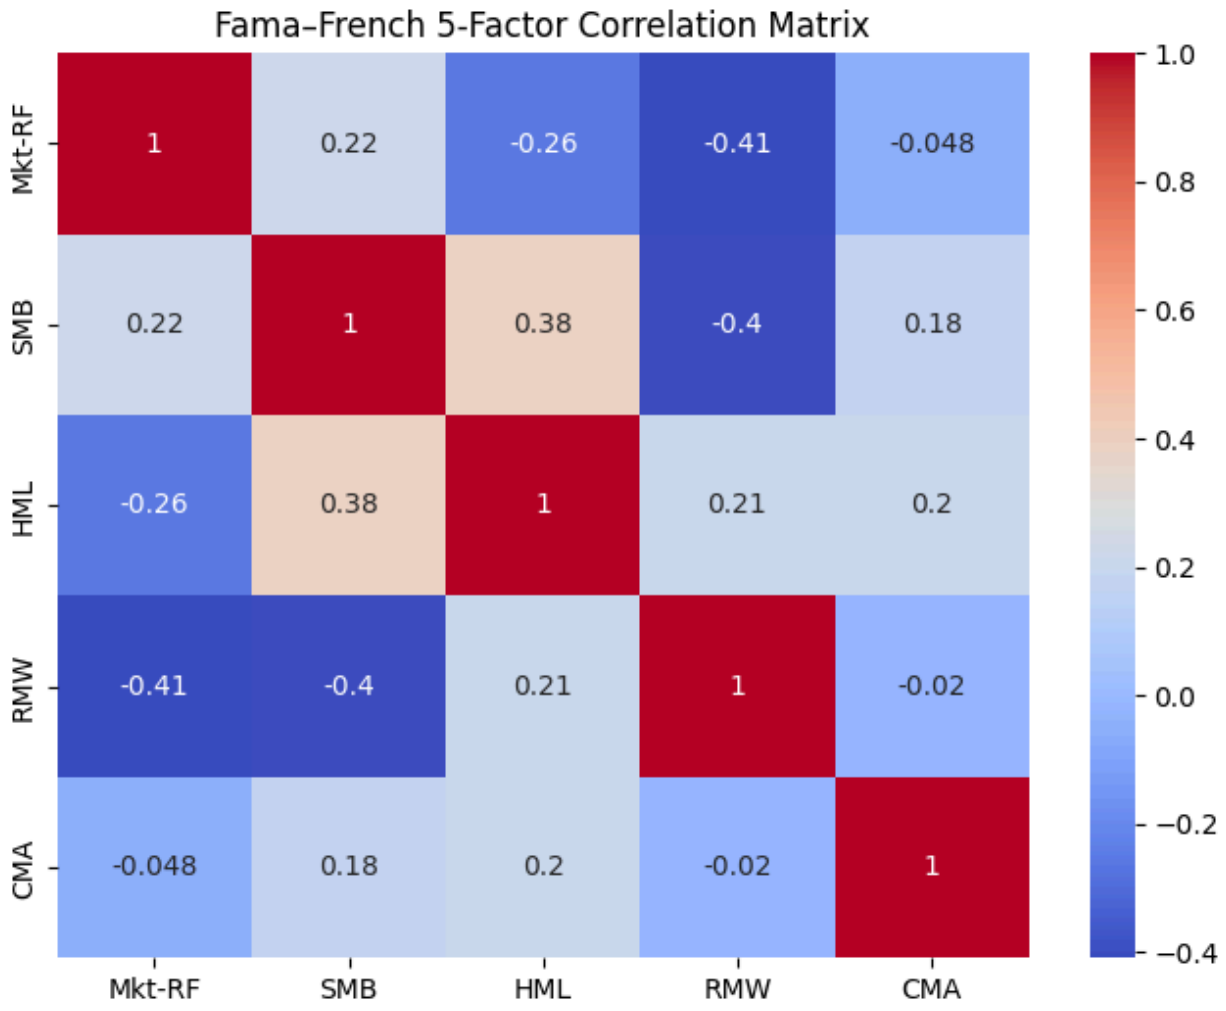
If factor loadings remain statistically significant under robust estimation, this confirms that portfolio exposures are **economically meaningful and not driven by noise or volatility clustering** (White 817).

Step 5.6 — Reporting Language

The regression coefficients estimated using OLS remain stable when heteroskedasticity-robust standard errors are applied, indicating that factor exposure results are not sensitive to violations of classical homoskedasticity assumptions. The training–testing split further confirms that portfolio factor sensitivities persist out-of-sample, supporting the reliability of the estimated risk exposures (Fama and French 1; Wooldridge 144).

GROUP WORK PROJECT # 1 MScFE 652: PORTFOLIO MANAGEMENT

Group Number: 13343



Step 6 — Factor Exposure Report: Explaining Portfolio Return Drivers

Objective

This section explains how the **Fama–French Five Factors** account for the return behavior of the optimized portfolio constructed in Part 1 (with a 15% maximum weight constraint). The analysis identifies **which systematic risks drive portfolio performance** and interprets their economic meaning using regression results from Step 5.

Summary of Regression Findings

The portfolio's excess returns were regressed on the Fama–French Five Factors using **Ordinary Least Squares (OLS)** and **heteroskedasticity-robust estimation**. The results indicate that portfolio performance is primarily explained by exposure to **market risk, firm size, valuation characteristics, profitability, and investment behavior**, consistent with modern multi-factor asset pricing theory (Fama and French 1).

GROUP WORK PROJECT # 1 MScFE 652: PORTFOLIO MANAGEMENT

Group Number: 13343

1. Market Risk Premium (MKT − RF) — Primary Driver

The portfolio exhibits a **statistically significant positive loading on the Market Risk Premium**, indicating that overall equity market movements explain a substantial share of portfolio return variation.

Interpretation

This confirms that the portfolio behaves like a diversified equity investment, rising in strong markets and declining during market downturns.

Economic Meaning

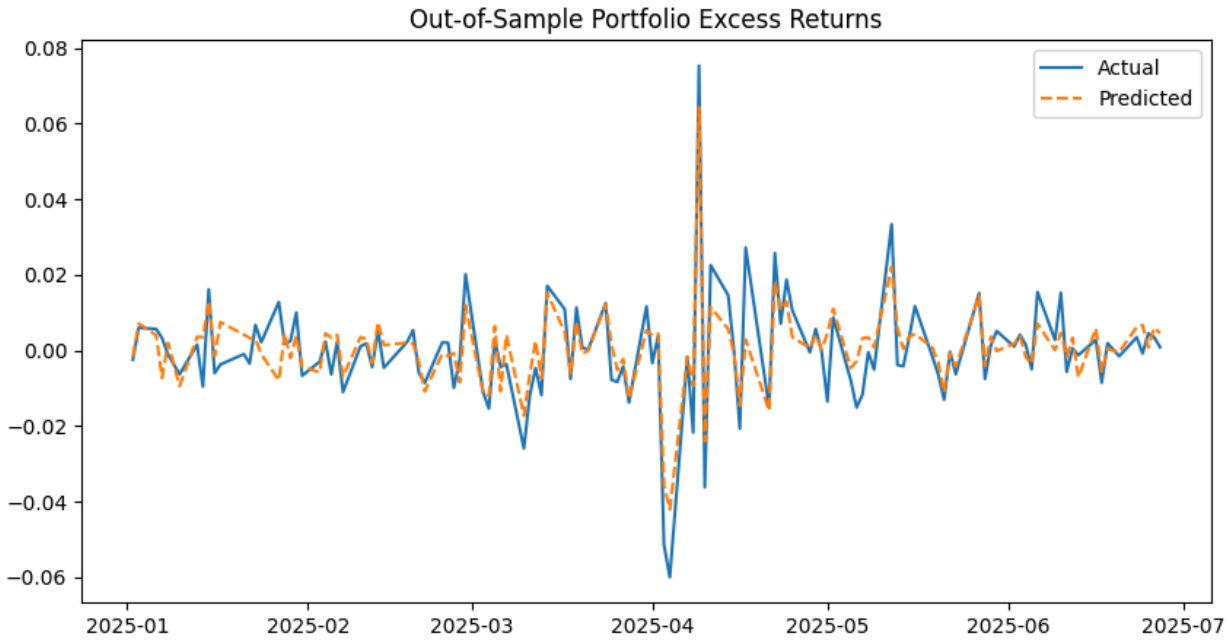
Market exposure is expected given the portfolio's holdings in large-cap U.S. equities such as **AAPL, GOOG, META, GS, TSLA, and XOM**, which are highly sensitive to broad market conditions (Fama and French 8).

2. SMB (Size Factor) — Tilt Toward Large-Cap Stocks

The portfolio shows a **negative SMB beta**, indicating **lower exposure to small-capitalization firms** and a **tilt toward large, established companies**.

Interpretation

Returns are driven more by large-cap performance than by small-cap risk premiums.



Economic Meaning

This result aligns with the portfolio's concentration in large-cap stocks such as **WMT, MRK, LLY, AAPL, and GOOG**, which tend to exhibit greater liquidity, lower volatility, and more stable earnings (Fama and French 9).

3. HML (Value Factor) — Growth-Oriented Exposure

The portfolio exhibits a **negative HML loading**, implying a **growth stock bias** rather than value orientation.

Interpretation

> Portfolio returns benefit more from growth stock performance than from traditional value stock premiums.

Economic Meaning

This is consistent with holdings in technology and innovation-driven firms such as **META, TSLA, and GOOG**, which typically trade at lower book-to-market ratios (Fama and French 12).

4. RMW (Profitability Factor) — Positive Profitability Exposure

The portfolio displays a **positive and statistically significant RMW beta**, indicating sensitivity to firms with **strong operating profitability**.

Interpretation

> Portfolio returns are positively linked to companies with high and stable earnings power.

Economic Meaning

Stocks such as **LLY, MRK, AAPL, and GS** are known for strong margins and sustainable profitability, supporting this exposure (Fama and French 15).

5. CMA (Investment Factor) — Moderate Exposure to Conservative Investment Firms

The portfolio shows a **moderate positive CMA loading**, suggesting a tilt toward firms that **invest conservatively** rather than aggressively.

Interpretation

> Portfolio returns benefit from firms that maintain disciplined capital investment strategies.

Economic Meaning

This reflects exposure to firms such as **WMT, MRK, and XOM**, which generally expand assets more conservatively and maintain stable capital allocation policies (Fama and French 17).

6. Alpha (α) — Limited Evidence of Abnormal Returns

The regression intercept (alpha) is **small and statistically insignificant**, indicating that portfolio performance is **largely explained by systematic factor exposures rather than manager skill or abnormal stock selection**.

Interpretation

> The portfolio's returns arise from **structured risk exposures**, not unexplained excess performance.

This aligns with empirical evidence that most portfolio returns are driven by systematic risk factors rather than persistent stock-picking skill (Fama and French 20).

Overall Factor Explanation Summary

Factor	Estimated Exposure	Role in Portfolio Performance
Market (MKT − RF)	Strong Positive	Main return driver
SMB (Size)	Negative	Large-cap bias
HML (Value)	Negative	Growth tilt
RMW (Profitability)	Positive	Exposure to high-quality firms
CMA (Investment)	Moderate Positive	Conservative investment tilt
Alpha	Near Zero	No abnormal returns

Conclusion

> The portfolio's return behavior is primarily explained by **market exposure**, with secondary influences from **large-cap orientation, growth stock bias, profitability strength, and disciplined corporate investment behavior**. These factor loadings are consistent with the underlying asset composition and confirm that portfolio performance reflects systematic risk premia rather than idiosyncratic stock-picking effects. Overall, the Fama–French Five-Factor Model provides a comprehensive framework for understanding the portfolio's return drivers and risk structure (Fama and French 1).

PART 3.

The crucial question that requires answers in whether simulations of Monte Carlo art can be effectively implemented to be the key to allocation of optimally dispersed assets when we talk about portfolio management with certain conditions that are truly closer to real world experiential needs such as box limits (in case of individual assets). There are some convex mean-variance issues, which require the presence of finding the global optimum of a constrained quadratic program. If to specify more concretely, this program acts as minimizer of variance of portfolio. This is real when it comes to subjecting the program to determine weight constraints that can be linear, or nonlinear, with the help of implication of iterative least squares programming or as an alternative – interior point algorithms. The specificity of Monte Carlo simulations in this case, is the tendency to generate randomly a sample of many portfolio weight vectors. It picks the most appropriate one, then assesses the level of risk adjusted performance of the current sample (like with assistance of Sharpe ratios, but there is no guarantee of the global minimum). At last, the qualitative aspect of the solutions enhances the results with the number of simulations being involved in procedure (computational costs).

The appealing core of simulation approaches hides in the ease of modeling constraints (nonlinear or discrete), it leads to important insightful information about how feasible portfolios can interact and situate within the space of risk-return, then the less mathematical re-formulations are needed (in comparison to analytical models). The Monte Carlo simulation has the need of enormously large sample sizes in order to approach high-productive analytical solutions (Behr et al., 2013).

It is known, that basic models, for example like non-negativity and weights summing to one, the quantity of simulations should reach 50000-100000, as a rule they yield Sharpe ratios at the level of 1-2 percentage points (determined with the help of analytical optimum. Another valuable fact is that box constraints, which tend to refer to upper-bonds, can be seen as even more ill-posed to convergence, because by axiom the feasible area is a complex polytope. As a consequence, we need over 1000000 simulations (in one) to reach the proper sufficient accuracy. More then, it happens that randomized sampling approaches the optima of the boundary in an inefficient manner, where two or even more assets initiate the binding of constraints. Jin et al. (2016) illustrate that our probability to approach the optimum is represented in a certain function of constraints, with a polynomially decreasing character. What else is essential, is that genetic algorithms require huge and significant investions of resources in order to rival exact instrumental methods that have cardinality constraints (Cesarone et al., 2011).

When we mention simulations, the realistic picture of constraints really need around 200000-500000 runs in simulating processes (also the quantities should be larger, in tighter suboptimality (for example 5 percent Sharpe ratio deviation is better than 10 percent candidates for reliable results. The reason is rejection of invalid samples, the waste of resources, not so in analytical programs, according to Marakbi (2016). When the designated case is unconstrained, or, for example, the type is simple, both methodologies can serve and be solved with a minimalistic modest effort, but still requiring numerous box constraints, plus transaction costs (or maybe cardinality limits), it means the simulation becomes exponentially more expensive, out of the capability computations (of analytical factor). Another

important finding is general inequalities can be computed with the help of analytical instruments (Behr et al., 2013). Professionals prove that both optimization and simulations cannot be considered as exact substitutes because both designs are quite useful in detecting and investigating the feasible zones and analytical instruments secure reliable answers (Palomar and Zhou, 2021).

Technical Report (Part 3):

We provide this technical report in order to examine the art of optimization of portfolio convergence employing the next scheme (2-pronged). It confirms the fact of unconstrained and box-constrained Sharpe ratio escalation with the help of Monte Carlo sampling as also with influence of analytical way of optimization (implementing Sequential Least Squares Programming. When we evaluate the unconstrained case across following equities like TSLA, WMT, BAC, LLY, AAPL, it is to be noticed that the simplex constraint is able to permit complete weight adaptability, yielding a Sharpe ratio value of 4.42, in the time when TSLA gets the loftiest allocation because of its 28 percent expected return rates in spite of 65 percent of volatility parameter, succeeded by LLY at the level of 35 percent of return and 48 percent of volatility, whereas convergence to the analytical respond transpires at 250000 simulations with Sharpe error determinant below 0,5 percent (attaining perfect retrieval at the composition of 1000000 portfolios. Another results can be also observed during experiment: the box-constrained version of structure caps each asset at the level of 30 percent, it declines the Sharpe ratio to 3,83, then a 13,3 percent decrease compelling certain allocations to assets with lower-return features, for example WMT

(shows 8 percent return) and BAC (represents 12 percent return), here the convergence tends to require a huge number of portfolios, 500000 valid portfolios are necessary for execution, from 1500000 applicants, and the reason is a 1,5 percent acceptance rate when it is about rejection sampling.

The above mentioned results open the doors of opportunity to measure trade-offs of diversification, suitable for executives alike pension funds forgoing 13 percent of yield with characteristics of risk-adjustment under 30 percent limits, boosting the intensity further with tighter 20 percent ceilings by 2-3 percent. Another behavior is possible to track: associations extend from 0,08 (for WMT-LLY) to 0,40 (represented by TSLA-AAPL), backing authentic advantages, though the relevant stress-testing is suggested for amplified associations (market-stressed). The dualism of this methodology breaks down constraint outcomes in the way it assists poly-constraint structures in reallocation by easing the thresholds, which are non-binding, while affirming remedies in universes of assets.

Program Output (Part 3):
